Remember:

- The introduced WAVELET analysis of functional skin perfusion data offers new visualization possibilities in a multidimensional space;
- It combines the benefits of time-resolved and frequency-resolved monitoring of skin perfusion;
- An additional advantage is the possibility to recognize and to localize artifacts in the records;
- From physiological point of view the WA is “MATHEMATICAL MICROSCOPE*” for functional perfusion visualization;
- This procedure is also very powerful by visualization of quasi-periodical phenomena (like earthquake, “el ninjo” and “tsunami” research)

PPGI perfusion studies VII:

Functional testing of rapid class allergy in dermatology*

Design of the study:

Measurement area on the inner side of the lower arm

Size: ca. 100 x 200 mm
~ 128 x 256 Pixel

Spatial resolution: 0,78 mm

Temporal resolution: 12 fps

Measuring field 1: histamine prick, 1 drop local

Measuring field 2: NaCl prick, 1 drop local

Measuring field 3: histamine, 0,05ml i.c.

Four PPGI-sequences
of 2 minutes duration:

- shortly before application
- 4 minutes after application
- 10 minutes after application
- 16 minutes after application

Expected data volume
per patient:
650 MByte (1 CD)

Summary

PPGI opens a new dimension for quantification of heterogeneity of dermal perfusion and for experimental and clinical micro vascular perfusion studies during vasoactive therapy.

In contrast to LDPI, PPGI offers

- simultaneous perfusion registration in all image points (camera instead of scanning)
- higher resolution

Optical coherence tomography (OCT)

Goal: destruction and stress-free, skin depth resolved visualization of tissue structure by time-resolved detection of scattered optical signal

OCT is an optical signal acquisition and processing method. It captures micrometer-resolution, three-dimensional images from within optical scattering media (e.g., biological tissue). It is an interferometric technique, typically employing near-infrared light. The use of relatively long wavelength light allows it to penetrate into the scattering medium. Starting from white-light interferometry for *in vivo* ocular eye measurements imaging of biological tissue, especially of the human eye, was investigated by multiple groups worldwide. A first two-dimensional *in vivo* depiction of a human eye fundus along a horizontal meridian based on white light interferometric depth scans was presented in 1990. Further developed in 1990/91 OCT with micrometer resolution and cross-sectional imaging capabilities has become a prominent biomedical tissue-imaging technique; it is particularly suited to ophthalmic applications and other tissue imaging requiring micrometer resolution and millimeter penetration depth. First *in vivo* OCT images – displaying retinal structures – were published in 1993. OCT has critical advantages over other medical imaging systems. Light in an OCT system is broken into two arm, a sample arm (biotissue probe) and a reference arm (usually a mirror). The combination of reflected light from the sample arm and reference light from the reference arm gives rise to an interference pattern, but only if light from both arms have travelled the "same" optical distance ("same" meaning a difference of less than a coherence length).

OCT implementation approaches:

- Use of ultra short pulses
- Utilization of limited coherence lengths
- Frequency coding of the laser probe beam

OCT implementation
option 2:
low coherence setup

After initial experiments with light sources limited bandwidth (a few nm) were relatively broad-band light sources available and used with high spatial coherence. In most cases, the OCT systems on superluminescent diodes with a few tens of nanometers bandwidth (typically 50 nm, equivalent to more than 50 microns resolution). First in the 1997 the leap from that standard resolution is successfully ventured up to the "ultra high resolution" (LED bandwidth > 100 nm, corresponding to less than 3 microns axial tissue resolution). The OCT tomograms allows today structure resolutions almost comparable with histological sections.

OCT implementation
option 3:
Frequency coding laser
setup (Chirp)

Chirp OCT is based on a continuous wave frequency modulated radar, but uses a tunable laser in the near infrared. As the full width at half maximum resolution of 16 mm is demonstrated with an external cavity laser, the chirp OCT becomes an alternative to conventional short coherence tomography with the advantage of a simplified optical setup.

Remember:

As a chirp (chirping of a cicada) refers to a signal whose frequency varies with time

CHIRP-OCT-Vorbild: FMCW Radar mit einem linearen Chirp

Für den Spezialfall eines linearen Chirp steigt die Frequenz linear mit der Konstanten k an:
 $f(t) = f_0 + kt$ und es gilt für den Zeitverlauf $x(t)$:

$$x(t) = \sin\left(2\pi \int_0^t f(t') dt'\right) = \sin\left(2\pi \int_0^t (f_0 + kt') dt'\right) = \sin\left(2\pi\left(f_0 + \frac{k}{2}t\right)t\right).$$

CHIRP OCT:

Block diagram and operating principle of the RWTH measurement concept, the core of which is a linearly tunable laser and a Michelson interferometer

The **Michelson interferometer** is the most common configuration for optical interferometry and was invented by Albert Abraham Michelson (1852 – 1931). An interference pattern is produced by splitting a beam of light into two paths, bouncing the beams back and recombining them. The different paths may be of different lengths or be composed of different materials to create interference fringes on a back detector.
 In 1907 Prof. Michelson was awarded with the Nobel Prize in Physics.
